Abstract

Introduction. Oral health is an integral part of the overall health of the body. Dental caries and periodontal diseases are conditions determined mostly by environmental factors and health behaviours. In order to cope with them it is often necessary to change eating habits and modify unhealthy behaviours.

Objective. The aim of the study is to evaluate the condition of the teeth and periodontium of young adults in the context of their lifestyle as a result of healthy and unhealthy behaviours.

Materials and method. The study covered a group of 250 students aged 19–22, in general good healthy, who were patients of the Centermed Clinic in Kielce. A diagnostic survey with a questionnaire was used as well as evaluation of a dental examination of the study participants.

Results. The results of analyses revealed that the examined students displayed numerous unhealthy behaviours connected with their diet, such as: skipping breakfast, having fizzy drinks, eating fast food, snacking between meals, and eating insufficient vegetables and fruit. There were correlations between negative health behaviours connected with diet and objective dental indices.

Conclusions. 1) The oral health of the examined young people, expressed with the indices studied (DMF, PD, SiC, BoP), requires definite improvement and dental intervention. 2) Young adults display numerous unhealthy behaviours despite being aware of the adverse influence on their general condition and oral health. 3) There was a correlation between the oral health of the examined young people and healthy and unhealthy behaviours.

Key words

health behaviours, lifestyle, conservative dentistry

Streszczenie

Cel pracy. Stan zdrowia jamy ustnej jest integralną częścią stanu zdrowia całego organizmu. Próchnica i choroby przyzębia są chorobami modyfikowanymi głównie przez czynniki środowiskowe i zachowania zdrowotne i do ich opanowania niejednokrotnie konieczna jest zmiana nawyków żywieniowych i modyfikacja zachowań antyzdrowotnych. Celem podjętych badań była ocena stanu uzębienia i przyzębia młodych dorosłych w kontekście ich stylu życia jako wyniku sumarycznego zachowań pro- i antyzdrowotnych.

Materiał i metody. Badaniem objęto grupę ok. 250 studentów w wieku 19–22 lat, ogólnie zdrowych, pacjentów przychodni Centermed w Kielcach. Podstawową metodą zastosowaną w pracy był sondaż diagnostyczny z zastosowaniem techniki ankietowania oraz ocena badania stomatologicznego badanych.

Wyniki. Wyniki przeprowadzonych analiz wykazały, że badani studenci prezentują liczne zachowania antyzdrowotne związane z dietą, takie jak: unikanie spożywania śniadań, picie napojów gazowanych, spożywanie posiłków typu fast food i podjadanie między posiłkami, jednocześnie ograniczając spożycie warzyw i owoców. Istnieją korelacje pomiędzy negatywnymi zachowaniami zdrowotnymi związanymi z dietą a obiektywnymi wskaźnikami stomatologicznymi.

Wnioski. 1. Stan zdrowia jamy ustnej badanej młodzieży wyrażony badanymi wskaźnikami (PUW, PD, SiC, BoP) wymaga zdecydowanej poprawy i interwencji stomatologicznej. 2. Młodzi dorośli prezentują liczne zachowania antyzdrowotne mimo świadomości ich negatywnego wpływu na ogólny stan zdrowia i stan zdrowia jamy ustnej. 3. Istnieje związek między stanem zdrowia jamy ustnej badanej młodzieży a zachowaniami pro- i antyzdrowotnymi.

Słowa kluczowe

zachowania zdrowotne, styl życia, stomatologia społeczna, stomatologia zachowawcza

INTRODUCTION

Oral health is an integral part of general health. Oral diseases are important components of noncommunicable diseases (NCDs), which continue to be a leading public health problem in the WHO European Region where tooth decay among 6-year-old children varies from 20% – 90%, depending on the country [1]. In the age group of 65 – 74-year-olds, the prevalence of those who have lost all their natural teeth ranges from about 20- to 50%. People without natural teeth may have functional problems, which detracts from their quality of life [2]. According to the WHO, dental caries and periodontal disease, similar to other lifestyle diseases such as excess weight, affect the whole of society, and their treatment and consequences of absence from work due to them are a considerable burden, both to the home budget and the State budget [3, 4, 5].

In accordance with research by the WHO, dental caries is one of the major problems of highly developed and developing countries [5], with dental caries among 6-year-old children accounting for 20% – 90% [1, 5]. The number of elderly people suffering from loss of teeth is 20% – 50%, which results in considerably lower quality of life in these people [3, 4, 5].

In recent years, there have been numerous studies on the influence of the condition of teeth and periodontium on advancements in the treatment of general diseases, especially coronary artery disease and diabetes [6]. The WHO decided to include dental prevention into chronic disease prevention programmes as an element of major importance for the general health and quality of life of patients [7, 8].

A consequence of the habits acquired during adolescence is the condition of teeth and the practices of young adults who are just beginning their independent life, and will be developing their views on health care and their own healthy routines, and passing this knowledge to and shaping the next generation, including health habits of their own children. The participants of the study were at the age suitable for starting their own families [9].

At the time of numerous programmes promoting broadly understood healthy lifestyle (practising sports, eating sufficient fresh vegetables and fruit, compensating for electrolyte deficits with isotonic drinks), the new problem of tooth erosion has emerged among people who take great care of their health and hygiene. Moreover, people from this group tend to use hard toothbrushes and brush their teeth just after a meal at the time of enamel demineralization, using the most abrasive brushing method – scrubbing. This can lead to irreversible changes on tooth surface and cavities not related to dental caries [10, 11]. This proves the necessity of education about oral hygiene in all groups of children and young people, even those who lead a healthy lifestyle.

OBJECTIVE

The aim of the study was to evaluate the condition of teeth and periodontium of young adults in the context of their eating habits.

MATERIALS AND METHOD

After obtaining the consent of the Bioethics Committee (No. 25/2017 6.10.2017), the study was carried out in 2018 – 2019 and covered a group of 253 students (139 women and 114 men), in general good health, who were patients of Centermed Clinic in Kielce. The participants were students at the Jan Kochanowski University and Kielce University of Technology who did not report systemic diseases in their medical history, and who gave their consent to the research. The study was conducted in a representative sample of students aged 19–22.

The basic method used in the study was a diagnostic survey with a questionnaire technique, as well as an intraoral dental examination of the participants. The dental examination evaluated:

- 1) DMF (decayed-missing-filled) index;
- 2) dental caries treatment index;
- 3) conservative treatment needs;
- 4) BoP (bleeding on probing) index;
- 5) OHI (oral hygiene index);
- 6) PD (pocket depth).

A diagnostic survey with a questionnaire constructed by the authors was used. The questionnaire contained 30 detailed questions about the lifestyle affecting the general state of health (diet, approach to exercise, care for rest, way of rest, presence of addictions), and questions about the care of teeth and dental care (knowledge of principles of oral hygiene, approach to dental treatment, frequency of office visits, current preventive measures). The questionnaire was created so that the approach to the topic of health reflected the way in which the participants approached the topic of oral health.

In the process of statistical analysis, the following methods of classical statistics were used:

- 1) Statistical description methods: the following were calculated for each variable:
 - arithmetic mean;
 - standard deviation.
- 2) Methods for evaluating significance of differences between compared groups:
 - Chi-square test to evaluate correlations between dependent and independent variables (level of significance was adopted at $p < 0.05$);
 - Mann-Whitney U test.
- 3) Correlation analysis method:
 - Pearson correlation coefficient (Pearson's r) to evaluate correlation strength between variables (level of significance was adopted $p < 0.05$);
 - Cramér's V .
- 4) All calculations were performed with STATISTICA 10 software.

RESULTS

Analysis of the correlation between dental indices and health behaviours connected with diet and other health behaviours: DMF index is a measurable (quantitative) variable and takes discrete values: 0, 1, 2, ..., 20. With such a 'fragmentation' of values it is very difficult to notice correlations, even at a positive performance of a test. Therefore, the variability range of DMF index is divided into four categories: very low, low, high and very high (Fig. 1).

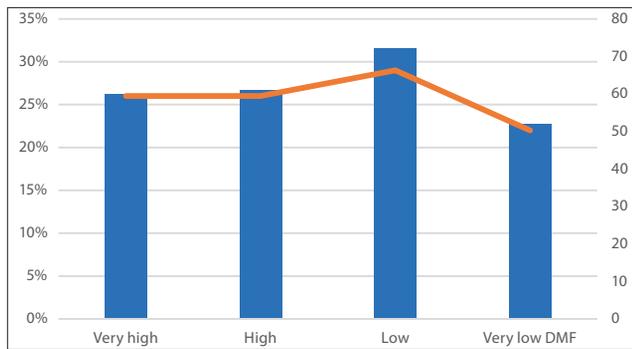

Figure 1. Distribution of people with respect to DMF index

Analysis of the correlation between tooth brushing frequency declared and DMF index revealed that less frequent tooth brushing resulted in higher DMF – 14 (61%) respondents who brushed their teeth once a day had a very high DMF. Similarly, the higher the OHI level, the higher the DMF index – 31 (60%) respondents with OHI 3 had very high DMF.

Many respondents who had a high and very high DMF index wrongly evaluated the condition of their teeth as good or average – 48 (49%) respondents with very high DMF index and 52 (52%) respondents with high DMF index. There was a weak correlation between DMF index and evaluation of the condition of one’s own teeth by the respondents. The lower the evaluation, the higher the DMF index.

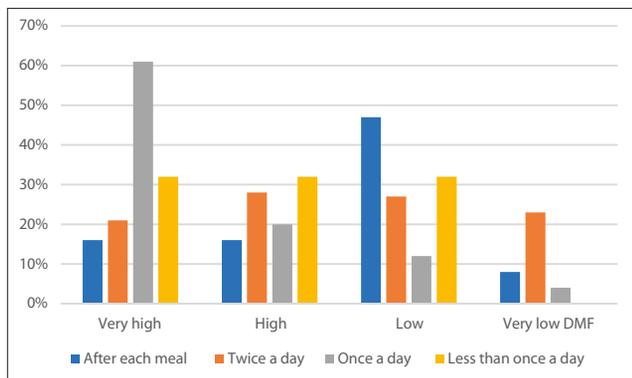

Figure 2. Correlation between DMF and tooth brushing frequency

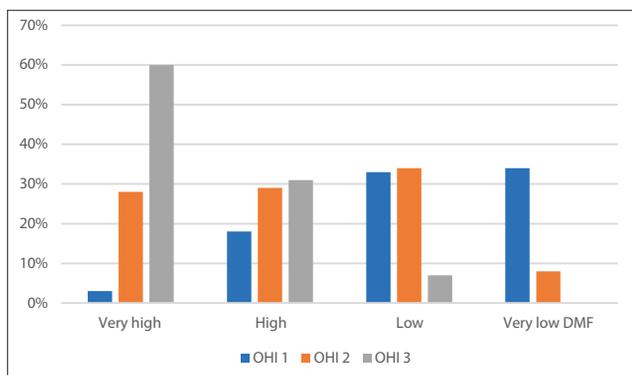

Figure 3. Correlation between DMF and OHI

The Mann-Whitney U test was performed for the DMF variable with all the variables which had two levels of values (e.g. gender). Similarly as in other tests, conclusions were drawn on the basis of p-value. If it was lower than the significance level $\alpha=0.05$ the hypothesis was rejected

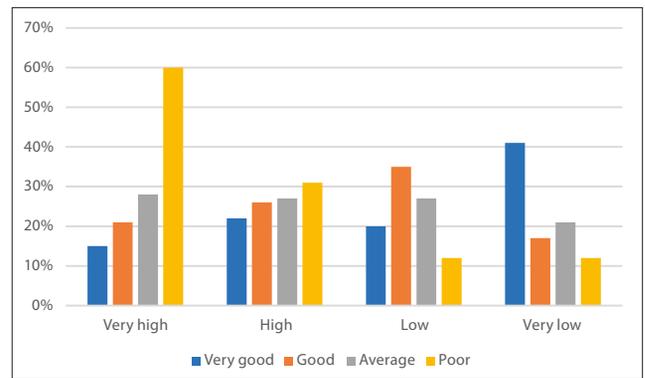

Figure 4. Correlation between DMF and subjective evaluation of condition of own teeth

about the equality of the median values, and were regarded as different. In only four cases the median values were different in the subgroups of the examined students. A higher median value of DMF variable was observed in the group of respondents who did not mention poor diet as an unhealthy behaviour. The median value of the DMF variable was lower in the group of participants whose parents took care of a diet rich in fruit and vegetables.

Table 1. Attitude to poor diet as an unhealthy behaviour vs. DMF value

U Mann-Whitney test, $p<0.05$

Poor diet as an unhealthy behaviour	DMF mean value	Rank sum	U	Z	p
Yes	9	4792	3711.00	2.2965	0.021
No	10	27086			

Table 2. Eating vegetables and fruit in childhood vs. DMF value

U Mann-Whitney test, $p<0.05$

Eating much vegetables and fruit in childhood	DMF mean value	Rank sum	U	Z	p
Yes	9	15779.5	6599.5	-2.24542	0.024

The treatment index is a measurable (quantitative) variable and takes values within the range of [0, 1]. Since there are many different values of this variable, its variability range is divided into four categories: very low, low, high and very high. Quartiles are used for this purpose, with the following values: $Q_1=0.4167$, $Q_2=$ Median value= 0.66667 , $Q_3=0.875$.

Distribution of the analysed variable is different for the female and male respondents. About 50% of men (46 respondents) had a high or very high treatment index, while about 40% of women (42 respondents) had such index values. Cramér’s V at the level of 0.19 indicated a weak correlation between the variables.

Analysis of the research results demonstrated that people who snacked on sweet buns -12 (50%) respondents, or sweets and salty snacks – 47 (51%) respondents, had a high or very high treatment index rather more frequently, similar to the group of respondents who declared using dental floss – 41 (58%) respondents]. The correlations were weak.

In the group of students participating in the research, a high or very high treatment index occurred the most frequently at OHI=2 – 48 (51%) respondents, and the least frequently at OHI=3 – 13 (25%) respondents. The correlation was quite noticeable ($V=0.29$).

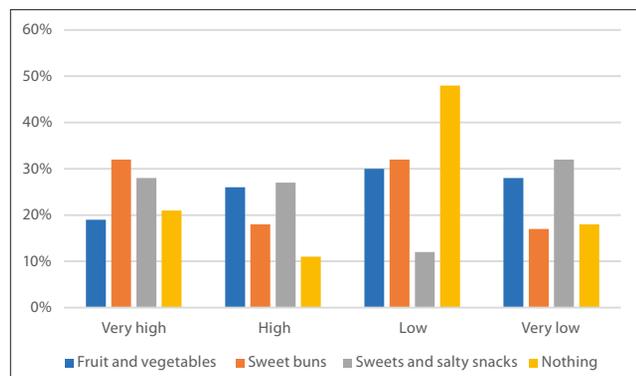

Figure 5. Treatment index vs. snacks between meals

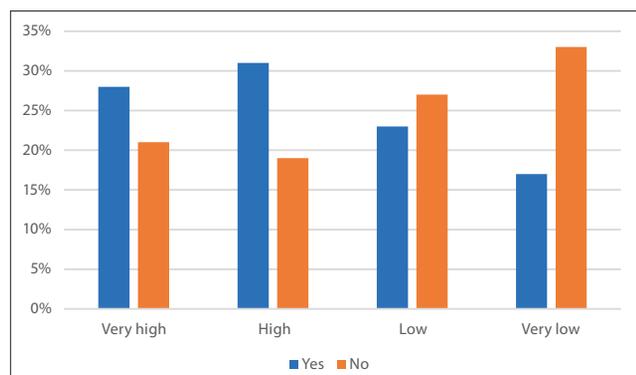

Figure 6. Treatment index depending on dental floss use

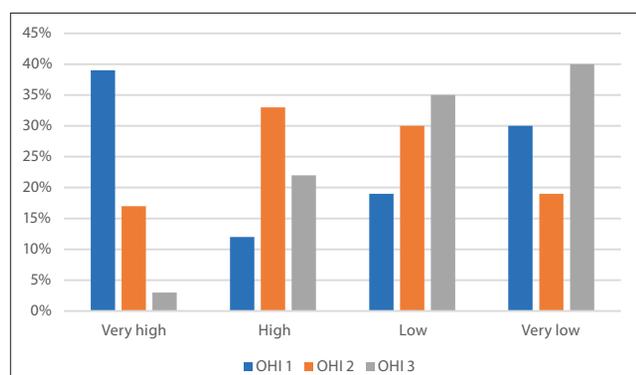

Figure 7. Treatment index vs. oral hygiene expressed in OHI

OHI is a quantitative variable already classified into four categories at the stage of questionnaire assessment. Consequently, it was assumed that it is a variable expressed solely in the ordinal scale. Moreover, the first category 'No plaque or calculus on tooth surface' was adopted for only one person. Due to so scarce representation among the respondents, this category was omitted in further statistical analysis.

The research results obtained show that the male respondents presented better oral hygiene than the female respondents. There was a lower share of women than men with OHI 1 – 69 (50%) men and 36 (31%) women, and higher with OHI 2 – 30 (21%) men and 55 (48%) women. The correlations for these two OHI levels are quite noticeable, even though, taking into account all OHI values, Cramér's V indicates weak interdependence.

Analysis of OHI values depending on the opinions concerning dental check-ups in a dentist's surgery as one of the measures to prevent oral cavity diseases, demonstrated

that among those who claimed that it is necessary to have one's teeth checked to keep them healthy, there were more respondents with OHI 1 – 47 (44%) respondents, and fewer with OHI 3 – 13 (12%) respondents. The correlation was weak.

A similar correlation was observed with respect to frequency of brushing the teeth. Among the respondents who brushed their teeth more frequently, there was a higher proportion of those with OHI 1 – 23 (70%) respondents, which means that they had less plaque or calculus on their teeth. On the other hand, among the respondents who brushed their teeth less often, there was a higher proportion of those with OHI 3, which means that there was more plaque or calculus on their teeth – 8 (35%) respondents brushed their teeth once a day. The respondents who did not brush their teeth every day were omitted from the interpretation, because there were so few of them (3). This correlation was stronger than in previous cases.

There was also a positive correlation between evaluation of the condition of one's own teeth and OHI: the better the evaluation of the condition own teeth, the higher the share with OHI 1 – 18 (46%) respondents who evaluated the condition of their teeth as very good, and 50 (48%) respondents who evaluated the condition of their teeth as good].

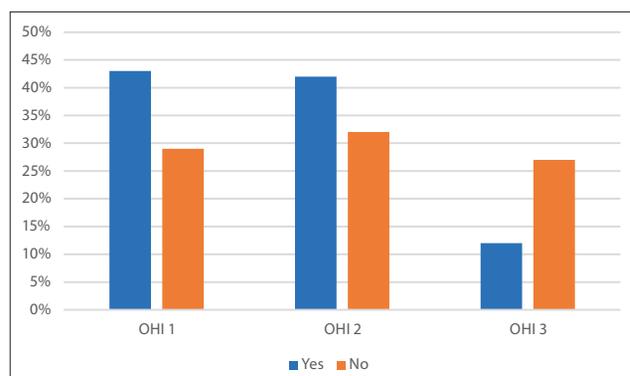

Figure 8. OHI and opinions concerning dental check-ups as a factor preventing dental caries

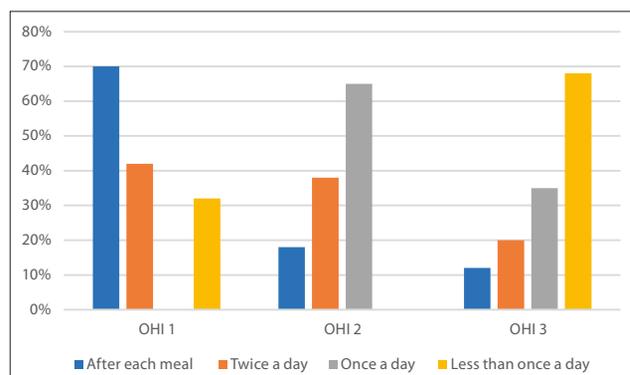

Figure 9. OHI vs. frequency of brushing teeth

BoP is a dichotomous variable indicating whether there is bleeding on probing (value 1) or not (value 0). It can be noticed that 78% of the respondents do not experience bleeding.

The analysis of the research results shows that among people who evaluate the condition of their teeth [11 (79%) respondents] and oral hygiene [17 (63%) respondents] as unsatisfactory, there is a considerably higher share of people with bleeding in comparison to other respondents. The correlation is noticeable.

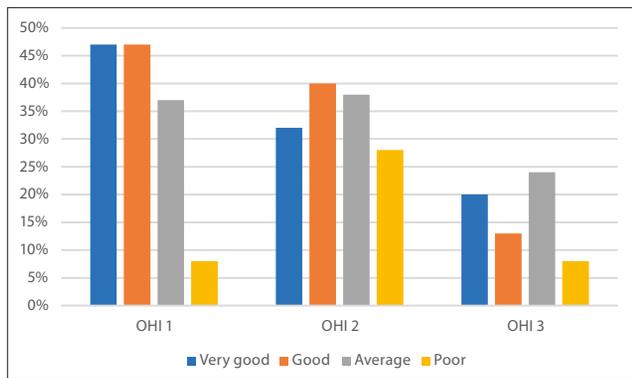

Figure 10. OHI vs. subjective evaluation of the condition of teeth

The results of the analyses demonstrate that there is a positive correlation between OHI and BoP index. The respondents with higher OHI are characterized by more frequent incidence of bleeding [39 (75%) respondents with OHI 3].

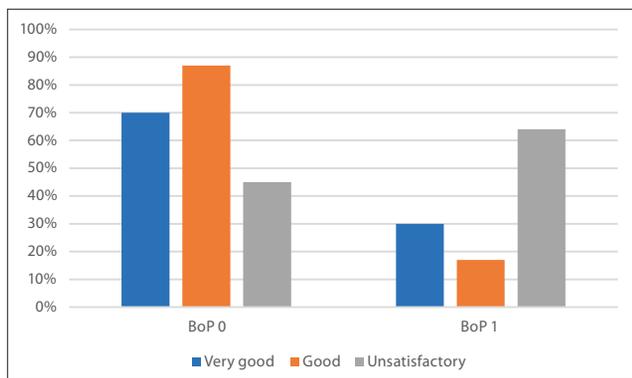

Figure 11. BoP index vs. subjective evaluation of oral hygiene

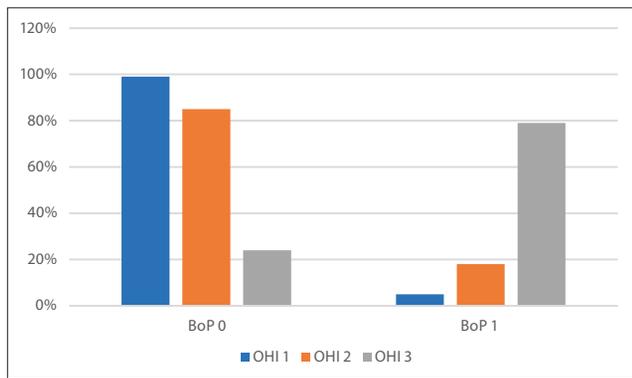

Figure 12. BoP index vs. OHI

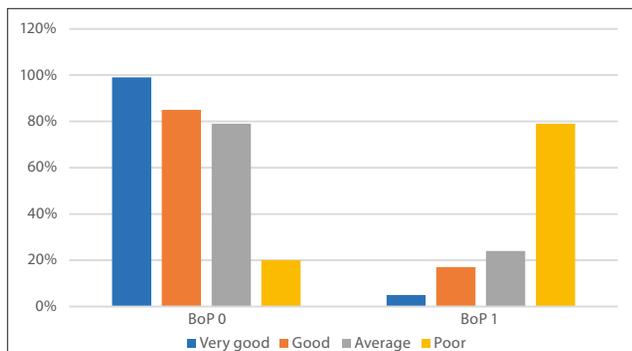

Figure 13. BoP index vs. subjective evaluation of teeth condition

The incidence and intensity of periodontium diseases with or without alveolar bone loss can be evaluated with the pocket depth index (PD). Physiologically, pocket depth should not exceed 2, while higher values suggest periodontal inflammation. Analysis of the PD index shows that the predominant depth of the periodontal pockets is 2, this proved to be the case in 214 (85%) respondents, with value 3 noted in 30 (ca. 12%) respondents. Other values were represented by marginal numbers.

Results of the analyses indicate that among people who claimed that it is necessary to have one's teeth checked to keep them healthy, a proportion of those with a higher pocket depth was over three times smaller – 5 (5%) respondents and 24 (17%) respondents, respectively.

Oral hygiene has a considerable influence on the health of the periodontium, expressed in periodontal pocket depth (PD); it is therefore not surprising that the higher the respondents' OHI, the bigger their share of deeper pockets – 20 (42) respondents with OHI 3. The correlation was very noticeable.

Analysis of the correlation between pocket depth and subjective evaluation of the condition of one's own teeth, demonstrated that among the those who assessed their dental health as unsatisfactory, there was a higher proportion of respondents with deeper pockets, compared to those who evaluated their dental health as good or very good – 19 (63%) respondents.

DISCUSSION

Numerous studies conducted worldwide have demonstrated a high incidence and intensity of dental caries among young people [12]. A positive aspect is the modern trend of improved health behaviours and prevention of neoplastic diseases, diabetes, cardiac illnesses, and other lifestyle diseases, but in many countries prevention of dental caries and periodontal disease is not a part of this trend [1, 3, 4]. The reason for this, as indicated by the analysis carried out by D. E. Piotrowska et al., may be the income level, source of income, and education level among rural and urban populations, as well as differences between these populations. This could imply that health disparities arise not only from economic constraints and unavailability of health care, but also from health attitudes and behaviours [13].

The current study also reveals a state of oral hygiene with a high incidence and intensity of dental caries, and other health behaviours. Results of the analyses show the incidence of dental caries at the level of 97%, 28% of the respondents had a DMF index at the level of 8.5 – 11.42; research analysis results also indicated the lower quartile at the DMF level of 6 and the upper quartile at the level of 12.5. The respondents with worse oral hygiene manifested in frequency of brushing the teeth – once a day in 14 (61%) respondents, and OHI value – 3 in 31 (60%) respondents, had a very high DMF index (above 12.5).

In similar research carried out among students in Lublin, the DMF index was 11.94, and among students in Białystok – 14.24 [13]. In Łódź, the incidence of dental caries was 70%, and average DMF index was 5.25 among those young people examined who displayed correct health behaviours. In another group of respondents, the incidence of dental caries was 80.4%, average DMF index – 7.17 [14].

A comparison between the research results obtained in the current study and the results obtained by other researchers shows that inflammation manifested by gum bleeding occurred less frequently in the group examined by the authors of this study. Analysis of the study results showed bleeding on probing in the case of 22% of the respondents. Bleeding was more frequent in respondents with high OHI – bleeding occurred in 39 (75%) respondents with OHI 3]. The distribution of OHI established in the current study indicated that the respondents' oral hygiene was not very good. Only one person had a complete absence of plaque/calculus, while about 58% of the students had plaque/calculus on at least 2/3 of the surface of the teeth. The male respondents – 69 (50%) participants, had OHI 1 more often than female respondents – 36 (31%) participants.

Among respondents in Kraków, 68.3% reported periodic gum inflammation manifested in gum bleeding, and 43.6% of the respondents had never had calculus removed [15].

In connection with the current results of actions aimed at improvement of knowledge about health behaviours and oral hygiene, and the unsatisfactory oral health of the respondents, it is necessary to undertake regular educational and preventive actions concerning lifestyle, including oral hygiene, in all age groups: children, young people and adults. There is abundant evidence demonstrating that the success of oral health promotion interventions delivered in the dental office depends on the character, values, personality, and people skills of the dental surgeon. Data show that if such professionals do not believe that oral hygiene instructions will

improve the health of their patient, then that professional will be less likely to practice an effective oral health promotion strategy [16, 17]. It is apparent that teaching health psychology to dentists would make oral health promotion more effective in dentistry [17]. As indicated by the WHO, the Ministry of Health should ensure that the mechanisms for intersectorial collaboration are carefully considered. Strategies include taxation and pricing, food labelling, school lunch policies and support of nutrition programmes [18].

CONCLUSIONS

1. The oral health of the examined young people, expressed with the indices studied (DMF, PD, SiC, BoP), requires definite improvement and dental intervention.
2. Young adults display numerous unhealthy behaviours related to diet, despite being aware of their adverse influence on general and oral health.
3. There is a correlation between the oral health of the examined young people and healthy and unhealthy behaviours.
